Background

MSF medical personal had faced syndromes of liver insufficiency among children in the different pediatrics hospitals. Investigating attributed causality (ischemic, viral, or toxic) was generally not possible due to the limited resources within these contexts. %2

In July 2015, increased admissions with similar syndrome were noted in Barnesville Junction Hospital (BjH) in Monrovia, Liberia. Children were reported to have consumed unprescribed conventional medications including paracetamol, antimarialars, and antibiotics, in addition to traditional treatments prior to hospitalization.

Lacking an infectious etiology, we hypothesized a toxic origin. We adopted a toxidrome-based approach, hypothesizing that the syndrome was associated with treatments consumed prior to hospitalization.

Methods

Case-series

Children over one month old admitted to BjH between July and December 2015 presenting at least two organ-specific symptoms with suspicion of toxicity were included. 29 plasma samples were transported to Laboratoire de Toxicologie, Hôpital Raymond Poincaré, France and tested for 1389 compounds and acetaminophen quantification.

Matched Case-control

To reach power of 80%, 30 cases and 60 controls were required. Therefore, the aim was to match the 30 cases with 60 hospital based- and 60 community based-controls.

The definition of cases used was:

**Definition**

Respiratory distress

Bradypnea, tachypnea, nasal flaring, inter- or sub costal retractions, grunting

Normal SpO2 in ambient air

SpO2 > 94% while breathing ambient air

In addition to one of the following symptoms

Absence of fever

<38.5°C arillary temperature

Hepatomegaly

>2 cm palpable below the right costal margin

Low blood glucose level

<50 mg/dl

The controls had to have at least one episode of non-trauma illness and were matched with the cases according to the following criteria:

**Table 1. Clinical and toxicological characteristics of the syndrome among children included in the case-series.**

</tbody>
</table>

Thirty percent (9/30) of the cases and 9.4% (5/53) of the controls enrolled in the case-control study died during hospitalization. Supratherapeutic doses of acetaminophen were higher among the cases than both hospital and community control groups, in contrast to the other potential hepatotoxic substances which were found to be similar across groups. Multivariable analysis revealed statistically significant higher odds of acetaminophen supratherapeutic doses and the toxic syndrome (Table 3).

Discussion

Clinical plausibility, toxidocing screening and statistical association, identified acetaminophen supratherapeutic doses as the main toxicant. Acetaminophen toxidrome has been rarely reported in children aged two years and younger, yet they remain the most susceptible due to their body weight of 10 kgs and less. While the toxicity of high single-dose of acetaminophen is well understood, the time-course of toxic effects induced by supratherapeutic staggered doses is not fully characterized, especially in low-weight children. A definitive diagnosis of a toxic cause requires the exclusion of non-toxic diagnoses. All these conditions were ruled out either by time-course effects or through comparison with hospital controls. There were no signs such as icterus and meningsism, suggestive of hemolytic-uremic syndrome or leptospirosis.

The study highlights a public health problem that has been underdiagnosed not just in Liberia, but possibly in all countries with unrestricted access to medications.
